Glutamate and Non-Glutamate Receptor Mediated Toxicity Caused by Oxygen and Glucose Deprivation in Organotypic Hippocampal Cultures

In vitro ischemia models have utilized oxygen, or oxygen and glucose deprivation to simulate ischemic neuronal injury. Combined oxygen and glucose deprivation can induce neuronal damage which is in part mediated through NMDA receptors. Severe oxygen deprivation alone however can cause neuronal injury which is not NMDA mediated. We tested the hypothesis that NMDA, or non-NMDA receptor mediated mechanisms may predominate, to induce neuronal injury following severe oxygen deprivation depending on the presence of glucose. We found that NMDA receptor blockade using dizocilpine (MK-801), DL-2-amino-5-phosphonovaleric acid (APV), or CGS 19755, was highly effective in reducing CA1 injury in organotypic hippocampal cultures, caused by complete oxygen and glucose deprivation. Complete oxygen deprivation alone however, caused CA1 neuronal injury which was not diminished using NMDA receptor blockade alone with MK-801 or APV, or in combination with AMPA/kainate receptor blockade using 6-cyano-7-dinitroquinoxalone-2,3-dione (CNQX). Neuronal protective strategies which act primarily through non-glutamate dependent mechanisms, including hypothermia, low chloride and calcium, and the free radical scavenger, α-phenyl-tert-butyl nitrone (PBN), provided neuronal protection against complete oxygen, as well as combined oxygen/glucose deprivation. Raising the pH using Hepes buffer during complete oxygen deprivation did not result in neuronal protection by NMDA receptor blockade. Partial oxygen deprivation alone, partial oxygen deprivation combined with glucose deprivation, glucose deprivation alone, and also glutamate exposure, all produced neuronal damage that was reduced by NMDA receptor blockade. The presence of glucose during complete oxygen deprivation appears to prevent glutamate receptor blockade from reducing neuronal injury in organotypic hippocampal cultures.

[Key words: glutamate, NMDA receptors, anoxia, hypoglycemia, ischemia, hypothermia, organotypic hippocampal cultures]

There is strong evidence that glutamate, which is known to be neurotoxic, contributes to ischemia induced neuronal injury (Buchan, 1990; Choi, 1990; Meldrum, 1990; Seisjo, 1992). In vivo studies have shown increases in extracellular glutamate in the brain during transient forebrain ischemia, and also following head injury (Benveniste et al., 1984; Faden et al., 1989; Kata- yama et al., 1990). Interruption of glutamatergic neuronal connections to hippocampal CA1 cells prior to transient forebrain ischemia can provide protection against CA1 ischemic damage suggesting that synaptic release of glutamate plays a role (Johansen et al., 1986; Ondera et al., 1986; Jorgenson et al., 1987). Moreover, glutamate receptor blockade of the NMDA and the non-NMDA subtypes can reduce neuronal damage following focal ischemia (Ozkan et al., 1987; Meldrum, 1990) and transient forebrain ischemia (Gill et al., 1987; Buchan and Pulsinelli, 1990). Glutamate receptor blockade can also protect dissociated neuronal cultures from damage induced by combined oxygen and glucose deprivation (Goldberg and Choi, 1993; Kaku et al., 1993).

The evidence for glutamate mediated damage following oxygen deprivation alone, is less convincing. Some investigators have reported reduced neuronal injury from oxygen deprivation using glutamate antagonists in dissociated cell cultures (Goldberg et al., 1987; Marcoux et al., 1990), or in acutely prepared hippocampal slices (Clark and Rothman, 1987). Other investigators have reported that glutamate receptor antagonists do not effectively reduce neuronal damage following oxygen deprivation alone (Aitken et al., 1988; Lipton and Lobner, 1990; Schurr and Rigor 1992; Friedman and Haddad, 1993; Haddad and Jiang, 1993). These previous studies raise the possibility that the nature and severity of the insult which is used to cause energy deprivation in these models may activate glutamate or non-glutamate receptor dependent mechanisms which in turn lead to neuronal damage.

We utilized organotypic hippocampal slice cultures to examine neuronal protection from different severities of oxygen and glucose deprivation. This model utilizes brain slices, prepared from the hippocampal formation of neonatal rats which are then maintained in a culture system for several weeks (Gahwiler, 1981; Newell et al., 1990; Vornov et al., 1994). Hippocampal slice cultures retain much of the anatomy, synaptic circuitry, and neurotransmitter receptors as the intact hippocampus (Zimmer and Gahwiler, 1984; Gahwiler, 1984, 1988; Vornov et al., 1991; Torp et al., 1992). These mature cultures are then deprived of...

Data indicate the ionic concentrations of the solutions used during exposure of the cultures to different insults. Additional oxygen deprivation experiments described were performed in HBSS with glucose, using a lower glucose concentration (5.6 mM) and a higher sucrose concentration (57 mM) than the concentrations described above.

Oxygen and or glucose and subsequent cell death can be assessed (Newell et al., 1990, 1995; Hsu et al., 1994).

We found a strong neuroprotective effect of NMDA receptor blockade on CA1 damage in organotypic hippocampal slice cultures, following combined oxygen and glucose deprivation; however, no protective effect of NMDA, and/or AMPA/kainate receptor blockade following severe oxygen deprivation alone. We also studied the effects of protective strategies including hypothermia, decreased extracellular chloride and calcium concentration, and a free radical scavenger α-phenyl-tert-butyl nitrone (PBN), on neuronal damage induced by oxygen deprivation alone, and combined oxygen and glucose deprivation. In addition we examined potential role of pH in mediating the lack of effectiveness of NMDA blockade in reducing neuronal injury following severe oxygen deprivation.

Materials and Methods

Preparation of cultures. Organotypic cultures of the hippocampus were prepared according to the method of Stoppini et al. (1991). Hippocampal slices were prepared from 4–7 d old neonatal rats (Sprague-Dawley; Buntin and Kingman Inc., Fremont, CA) by removing the brain, dissecting the hippocampal formation and making transverse slices (400–500 μm) using a McIlwain tissue slicer. Slices were then placed in Gey's balanced salt solution supplemented with glucose (final concentration 6.5 mg/ml, or 33.6 μm), for 1 hr at 4°C. Individual slices were then transferred to 28 mm sterile transparent Anocel membranes (Whatman Inc., Clifton, NJ). Membranes were placed in 6 well culture trays with 1.5 ml growth medium consisting of 50% MEM (GIBCO Laboratories, Grand Island, NY) supplemented with Hepes and sodium bicarbonate, 25% Hanks' balanced salt solution, 25% horse serum, and glucose to a final concentration of 6.5 mg/ml. The cultures were then grown at 36.5°C, 90–100% humidity, 5% CO2. Antibiotics were not added to the medium. The culture medium was changed every 2 d. All cultures used in this study were grown for 10–14 d in vitro, and only those cultures with dentate, CA1, and CA3, were used. Propidium iodide (PI) (Sigma Chemical Co., St. Louis, MO), which rapidly enters cells with damaged membranes and becomes brightly fluorescent after binding to nucleic acids, was added (0.5 μg/ml) to the culture medium as an indicator of neuronal death during the experiment. By itself, PI is non toxic to neurons and has been used as an indicator of neuronal membrane integrity and cell viability (Macklis and Madison, 1990). After 24 hr, the cultures were examined using a Nikon Diaphot (Nikon Corp. Tokyo, Japan) inverted fluorescent microscope to verify that the cultures were healthy prior to insult exposure. Animals were cared for according to the guidelines of the University of Washington animal care committee.

Preparation of compounds. The NMDA antagonists MK-801, APV, and the AMPA/kainate receptor antagonist CNQX were obtained from Research Biochemicals Inc., Natick, MA. The competitive NMDA antagonist CGS 19755 (Lehmann et al., 1988) was kindly provided by Ciba Geigy. α-Phenyl-tert-butyl nitrone (PBN) was obtained from Sigma Chemical, St. Louis, MO. The compounds were prepared as a 10 μM solution in glucose-free HBSS except CNQX which was prepared as a 5 μM solution. It was necessary to dissolve it first in basic conditions, as was then titrated it to a neutral pH. Each compound was added to the buffer before the insult and to the culture medium that was...
Figure 3. Comparison of cell counts to PI imaging to assess CA1 damage. Illustration of a control hippocampal slice culture (no insult). A, Low power; B, high power of intact CA1 pyramidal cells. Scale bars: 100 μm in 1A, 2A; 500 μm in 1B, 2B. C, Propidium iodide fluorescence of slice cultures 2 d after exposure to either (upper) no insult, or (lower) 50 min of oxygen and glucose deprivation. DG, dentate gyrus. D, Regression analysis illustrating the results of a comparison between the cell counting method and the
used for the incubation following the insult, as small aliquots to give the final concentrations described. For the dose-response curve, a 10 mM stock solution of MK-801 was progressively diluted in glucose-free HBSS.

Induction of neuronal damage using various insults. Insults were induced using previously described methods (Newell et al., 1990, 1995). The cultures were rinsed 3X in glucose-free, or glucose containing HBSS, and then placed in 1.5 ml of HBSS without glucose for the oxygen/glucose deprivation, or in HBSS with glucose for oxygen deprivation. All HBSS solutions were adjusted to the same molarity with sucrose. For the low chloride low calcium experiments, calcium was omitted from the HBSS and sodium gluconate was used instead of sodium chloride. The composition of the solutions used is given in Table 1. Drug or vehicle was added 10–15 min before exposure to the insult. The temperature of each individual culture well was maintained to be at 37°C with an electronic thermometer, and was carefully controlled to be equivalent in all cultures, to ensure that the results were independent of changes in temperature. For the hypothermia experiments, the temperature of the cultures was maintained at 33.0°C during initial transfer to the HBSS, and during the exposure to the insult. Following the insult, the cultures were then placed in growth medium which had been warmed to 37°C and were incubated at this temperature for 40–48 hr until analysis.

The cultures were transferred into an anaerobic chamber (Forma Scientific) which was preequilibrated to 37°C and had an atmosphere of 0% oxygen, 10% hydrogen 5% CO₂, and 85% nitrogen. The hydrogen was present for interaction with a palladium catalyst which maintained the oxygen concentration at 0%. An oxygen meter which utilized a Clark microelectrode was present at all times to confirm anoxic conditions. Following equilibration in the medium, (for 10 min) the culture tray was placed in the anaerobic chamber at 37°C for 35 min. Figure 1 illustrates the measurement of the time course of the oxygen level at the interface membrane which contains the cultures. Upon removal of the tray from the anaerobic chamber, membranes were transferred to prewarmed growth medium containing drug or vehicle in the same concentrations used for the culture treatment. The growth medium also contained propidium iodide at a final concentration of 0.5μg/ml. The cultures were transferred back to a CO₂ incubator at 36.5°C for 40–48 hr before they were evaluated for cell death.

In cultures exposed to glutamate, either MK-801 (30 μM) or an equivalent amount of buffer was added to the culture medium, 10 min before addition of glutamate. Glutamate was then added at a final concentration of 10 mM and incubated at 37°C for 30 min. The cultures were then removed from this medium, rinsed, and placed in fresh growth medium containing PI and either MK-801 or buffer. The cultures were then transferred back to the CO₂ incubator at 36.5°C for 40–48 hr before they were evaluated for cell death, using PI fluorescence.

Assessment of cell death by image analysis using PI. The intensity of propidium iodide fluorescence in the CA1 subfield of the cultures was used as an index of cell death. The first measurement of fluorescence intensity was performed between 40–48 hr, following the initial insult. The cultures were examined using a Nikon Diaphot inverted fluorescence microscope. Fluorescent images were obtained using a Dage 72 CCD camera (Michigan City, IN), and were digitized, using OPTIMAS image analysis software (Bio-Scan, Inc., Edmonds, WA) running under MICROSoFT WINDOWS. Forty to 48 hr after the initial "ischemic" insult, the remaining neurons were killed by exposing the cultures to 3 hr of anoxia. The fluorescence intensity, 24 hr after 3 hr of anoxia, was set equal to 100% damage to CA1, and was then compared to the fluorescence intensity following the initial insult. The integrated gray value (the numerical value for the fluorescent intensity) in the region of interest (ROI) was calculated by the computer and was used as an index of 100% toxicity. Computer analysis of each image was performed by creating an ROI around the CA1 pyramidal cells 24 hr after anoxia exposure (Fig. 2). The images from the same culture taken at 48 hr following the insult were then recalled and analyzed by superimposing the ROI which had been created from that identical region following the 3 hr anoxia exposure. The integrated gray values (fluorescent intensity) from the CA1 subregion following the initial insult were then expressed as a percentage of the value obtained following 3 hr of anoxia. The values were averaged for each group and compared. All values were expressed as mean ± SEM. Statistical analysis of the results was performed using Student’s t test and the Mann-Whitney test with Bonferroni correction for multiple comparisons where appropriate. Significant differences were considered at the p value <0.05.

Comparison of PI fluorescence and histological analysis for quantification of neuronal injury. We compared the results of histologic evaluation of neuronal damage to the amount of neuronal damage determined by the computerized imaging system in order to examine the validity of the quantification method used in this study. Groups of cultures were randomized to be assessed by either histologic evaluation or calculation of percent fluorescence using computerized imaging of propidium iodide staining (12 cultures in each group). Parallel groups of cultures were then exposed to either no insult, or 30, 40, or 50 min of anoxia/hypoglycemia in HBSS to achieve varying degrees of neuronal damage. The cultures were then incubated in growth medium with PI for 2 d (40 hr). All of the cultures were then imaged using the inverted fluorescent microscope, digitized, and then stored for analysis. The groups for histology were then fixed in 3% paraformaldehyde in phosphate-buffered saline, then dehydrated in a graded series of ethanol, followed by embedding in paraffin. Sections of 5 μm thickness were then cut, stained with cresyl violet stain. The groups for percent fluorescence were placed in anoxic conditions at 36.5°C for 3 hr. These cultures were then reimaged 24 hr after the anoxic exposure.

The CA1 region of each culture was examined using light microscopy. Dead pyramidal neurons were identified by characteristic pyknotic nuclei and disappearance of the normal cytoplasm and cellular architecture (Brown and Brierly, 1972). A quantitative analysis of cell death in the CA1 region of each culture was performed using a modification of the sampling method described by Bolender et al. (1991). Multiple high power fields were examined and internal cursors were used to delineate the cells to be counted in multiple samples of each CA1 region. The number of dead cells was divided by the number of dead and live cells, and multiplied by 100 to yield a percentage of dead cells in each sample. This process was repeated for each of the cultures and the results were averaged within each group, exposed to the different durations of the insult. The percentage of dead cells derived using the counting method was then compared to the percent fluorescence obtained using the computerized imaging system, in parallel groups of cultures exposed to the same insults, using regression analysis. The correlation between PI fluorescence and cell counting was also performed using severe oxygen deprivation with glucose (5.6 mM and also at 33.6 mM), to cause CA1 damage. The pH measurements. The pH was measured in the HBSS in each culture well in groups of cultures in the anaerobic chamber immediately following the standard exposure to complete oxygen and also oxygen/glucose deprivation. The pH in the HBSS containing glucose was slightly lower 6.63 ± 0.05 versus 6.77 ± 0.083 in the HBSS without glucose (p = 0.04 using t test). Measurements were performed using a calibrated pH microelectrode (Physitemp, Clifton, NJ) and pH meter (Beckman Instruments, Fullerton, CA). In a separate set of experiments, 10 mM Hepes buffer was added to portions of HBSS with and without glucose. The pH was adjusted to 7.4 prior to anoxic exposure and then measured again in each of the culture wells following exposure as described above.

Results
Comparison of PI fluorescence and histological analysis. The evaluation of CA1 damage 2 d after a graded severity of combined oxygen and glucose deprivation was performed by either the cell counting method or the PI fluorescence method as described above. Regression analysis revealed a strong significant correlation between the two assessment methods (r = 0.99, Y = 2.46 + 0.97x, p = 0.002) (Fig. 3D). The results showed a similar correlation between PI fluorescence and histological analysis.
Glutamate and Non-Glutamate Toxicity in Hippocampal Cultures

ysis revealed the following significant correlation; $r = 0.99$, $Y = 2.03 + 1.0X$, $p = 0.001$.

Oxygen deprivation with 5.6 mm glucose present caused CA1 damage indicated by percent dead cells and PI fluorescence as follows: after no anoxia $0 \pm 0\%$ dead cells, $0 \pm 0\%$ PI fluorescence, after 30 min anoxia $18.1 \pm 2.0\%$ dead cells, $17.6 \pm 6.3\%$ PI fluorescence, after 35 min, $72.6 \pm 3.6\%$ dead cells, $69.6 \pm 10.3\%$ PI fluorescence, and after 55 min, $100 \pm 0\%$ dead cells, $98.4 \pm 2.8\%$ PI fluorescence. Regression analysis revealed the following significant correlation; $r = 0.99$, $Y = 0.3 + 1.0X$, $p = 0.0002$.

Complete oxygen + glucose deprivation

NMDA receptor blockade was protective against delayed neuronal degeneration following severe oxygen (0%) plus glucose deprivation for 35 min. MK-801 showed CA1 protection in a dose-dependent manner (Figs. 4, 5). APV (300 μM) and CGS 19755 (100 μM) also provided significant protection from this insult (Table 2). We then investigated the protective effects of several other neuroprotective treatments, and also found significant protection against CA1 damage. These treatments included reduced temperature (33°C) during the insult (hypothermia), reduced calcium and chloride in the HBSS during the insult (low calcium, low chloride, composition given in Table 1), and also treatment with the spin trapping free radical scavenger PBN (100 μM) (Table 2). All of these treatments provided significant neuroprotection against CA1 damage.

Complete oxygen deprivation (anoxia)

Complete oxygen deprivation for 35 min, produced by placing cultures in anaerobic conditions with glucose present (33.6 mm), caused damage to CA1 neurons which was not blocked by NMDA receptor blockade with MK-801 (30 μM) or APV (300 μM) (Fig. 5, Table 3). The same insult for a shorter time period (30 min) produced less neuronal damage, and for a longer time...

Data illustrate the effect of neuroprotective strategies in reducing the percentage fluorescence, used as an indicator of neuronal damage, in the CA1 region of the hippocampal slice cultures caused by severe oxygen and glucose deprivation. The NMDA antagonists MK-801, APV, CGS-19755, and also hypothermia, low chloride and low calcium in the buffer during the insult, and the free radical spin trapping compound PBN all provided significant protection to CA1 against damage from this insult (Student's t test) (all values given as mean ± SEM; n = 12 for each group).

period (40 min) produced more neuronal damage and neither were affected by NMDA receptor blockade using MK-801 (30 μM) (Fig. 6A). The AMPA/kainate receptor antagonist CNQX (300 μM), was also not neuroprotective against this insult when administered alone, or in combination with MK-801 (30 μM) or APV (300 μM) (Table 3).

To ensure that the high glucose used in the culture medium (33.6 mM) was not responsible for the lack of protection seen with NMDA receptor blockade, we performed an additional experiment with the glucose reduced from 33.6 mM to a more physiological concentration, 5.6 mM, in the HBSS during the complete oxygen deprivation. Under these conditions, MK-801 (30 μM) still did not provide any protection against two different severities of neuronal damage induced by complete oxygen de-

Data demonstrate the effect of neuroprotective strategies in reducing the percentage fluorescence, used as an indicator of neuronal damage, in the CA1 region of the hippocampal slice cultures caused by severe oxygen deprivation, with glucose present (33.6 mM). In contrast to the protective effect seen with oxygen and glucose deprivation, glutamate receptor blockade using the NMDA antagonists MK-801 or APV, alone or in combination with the AMPA/kainate receptor antagonist CNQX, did not reduce neuronal damage caused by severe anoxia. There was also no reduction in anoxia-induced CA1 damage by CNQX alone. Hypothermia, low chloride and low calcium in the buffer during the insult, and the free radical spin trapping compound PBN all provided significant protection to CA1 against damage from this insult (Student's t test) (all values given as mean ± SEM; n = 12 for each group).
Blockade against severe oxygen deprivation cannot be explained by the higher glucose concentration (test). The results indicate that the lack of protection by NMDA receptor blockade against severe oxygen deprivation cannot be explained by the higher glucose concentration used in the other experiments.

Figure 7. Effect of MK-801 (30 μM) on CA1 damage caused by complete oxygen deprivation at two different severity levels (35 and 40 min) with 5.6 mM glucose present. There was no significant difference at either level of injury (p = 0.71 at 35 min, p = 0.85 at 40 min, by t test). The results indicate that the lack of protection by NMDA receptor blockade against severe oxygen deprivation cannot be explained by the higher glucose concentration used in the other experiments.

Since we did not find any protection against complete oxygen deprivation using glutamate antagonists, we then examined the effects of other neuroprotective strategies which act primarily through non-glutamate dependent mechanisms. As with oxygen plus glucose deprivation, hypothermia (33°C), low calcium and chloride, and the free radical scavenger PBN (100 μM) all provided significant protection against complete oxygen deprivation (Table 3).

Partial oxygen deprivation (hypoxia)

Partial oxygen deprivation produced by placing cultures in an environment of 4% oxygen, in glucose containing HBSS, required 2 hr of exposure time to produce significant neuronal damage in CA1. Blockade of NMDA receptors using MK-801 (30 μM) significantly reduced neurotoxicity in CA1 caused by this insult (see Table 4).

We then examined the effect of NMDA receptor blockade on CA1 damage caused by partial oxygen deprivation combined with glucose deprivation, as well as glucose deprivation alone, and also damage caused by addition of glutamate.

Glucose deprivation with partial oxygen deprivation

Partial oxygen deprivation, using 4% oxygen, combined with complete glucose deprivation required only half the exposure time (1 hr) to produce equivalent damage to CA1 neurons as the same level of oxygen deprivation with glucose present. Exposure to this insult for 1 hr produced neuronal degeneration in CA1. Significant neuronal protection was observed in the presence of MK-801 (30 μM), indicated by a marked reduction in CA1 fluorescence (see Table 4).

Glucose deprivation

Deprivation of glucose produced by incubating the cultures in glucose free medium required 2.5 hr also produced CA1 damage. There was also prominent dentate damage observed with this insult. Blockade of NMDA receptors with MK-801 (30 μM) significantly reduced fluorescence in CA1 (see Table 4).

Data demonstrate the significant protective effect of NMDA receptor blockade using MK-801 in reducing the percentage fluorescence, used as an indicator of neuronal damage, in the CA1 region of the hippocampal slice cultures caused by partial oxygen deprivation (4% O2) without and with glucose (33.6 mM), glucose deprivation with oxygen present, and exposure to glutamate (10 mM) for 30 min (Student's t test) (all values given as mean ± SEM; n = 12 for each group).
Addition of glutamate (10 mM) to the culture medium for 30 caused marked neuronal damage to all the hippocampal subfields, when examined 40–48 hr later. Blockade of NMDA receptors using MK-801 (30 μM) significantly reduced delayed fluorescence in CA1 caused by the glutamate (see Table 4).

**Discussion**

These results indicate that there are different mechanisms that produce neuronal damage during severe anoxia in the presence or absence of glucose. Glutamate receptor mediated neurotoxicity appears to be an important component of neuronal injury under *in vitro* conditions when neurons are deprived of oxygen and glucose. With severe oxygen deprivation in the presence of glutamate however, neuronal injury occurs which is not prevented by glutamate antagonists, but can be prevented using other strategies which provide neuroprotection primarily through other mechanisms.

These findings are in agreement with previous findings from other laboratories using dissociated neuronal cultures, or acutely prepared hippocampal slices. NMDA receptor antagonists have not been found to provide neuroprotection in these models against severe oxygen deprivation (Aitken et al., 1988; Lipton and Lobner, 1990; Friedman and Haddad, 1993), but do provide protection against combined oxygen and glucose deprivation (Newell et al., 1990, 1995; Goldberg and Choi, 1993; Kaku et al., 1993; Vornov et al., 1994). NMDA receptor blockade is ineffective in preventing intraneuronal calcium accumulation, which is associated with delayed neuronal death (Seisjo and Bengtsson, 1989; Hartly et al., 1993), due to severe anoxia alone. Lipton and Lobner (1990) also showed in acutely prepared hippocampal slices exposed to complete oxygen deprivation, that NMDA receptor blockade failed to block increases in intracellular calcium levels. Using dissociated cell cultures, Friedman and Haddad (1993) found that severe anoxia caused a rapid increase in intracellular calcium in neurons which was also not prevented by combined NMDA and non-NMDA receptor blockade using MK-801 and CNQX. NMDA antagonists are reported to reduce neuronal damage produced by extremely long exposures (8 hr) to low oxygen (Goldberg et al., 1987). Due to the experimental design of this study, in which the neuronal cultures were submerged in buffer, it was stated that initial oxygen deprivation was probably partial. We have also found a delay (15–20 min) in the reduction in oxygen concentration in cultures submerged in 1.5 ml of buffer (data not shown). However, no delay was observed in this study, when interface cultures were used (Fig. 1). Similarly, Marcoux et al. (1990) demonstrated that NMDA receptor blockade reduced calcium accumulation in dissociated neurons exposed to a 1% oxygen environment for 5 hr. These results are consistent with our finding that NMDA receptor blockade can protect neurons against oxygen deprivation alone of reduced severity (4% oxygen for 2 hr in the present study).

The mechanism responsible for the different protective effects of NMDA receptor blockade against neuronal damage produced by severe oxygen deprivation alone and severe combined oxygen and glucose deprivation, is unclear. The two insults cause a similar degree of injury in this system. Increased intracellular calcium is thought to play an important role in the pathogenesis of ischemic neuronal damage (Andine et al., 1988; Seisjo and Bengtsson 1989; Lobner and Lipton 1993). It has been proposed that NMDA antagonists cannot effectively prevent increased in intracellular calcium in severe ischemia due to massive neuronal depolarization and ATP depletion (Wieloch et al., 1989; Seisjo, 1992). Under these circumstances, calcium may enter cells through a variety of pathways, and energy dependent calcium extrusion mechanisms can fail (Kass, 1982; Lipton and Lobner, 1990; Seisjo, 1992; Lobner and Lipton, 1993). This explanation could account for the differences observed between complete oxygen deprivation and the more prolonged insults in our experiments, however it would not explain why NMDA antagonists protect against damage induced by complete oxygen and glucose deprivation which should cause the most marked energy deprivation.

Another possible explanation for the present findings is that oxygen deprivation in the presence of glucose may induce anaerobic metabolism, which could lower pH. At low pH, NMDA receptors can be inactivated (Giffard et al., 1990; Tang et al., 1990; Kaku et al., 1993), and under these circumstances lactate accumulation may occur, and other mechanisms of cell toxicity may predominate. Kaku et al. (1993) found that although a lower extracellular pH provided a protective effect against damage to dissociated neuronal cultures deprived of oxygen and glucose, the addition of glutamate antagonists provided additional protection against this insult at a pH of 6.4. This was lower than the pH in the buffer solution following complete oxygen or oxygen and glucose deprivation in our experiments. Measurement of the pH in the HBSS immediately following each of these insults revealed only a slightly lower pH in our cultures exposed to oxygen deprivation alone versus those exposed to combined oxygen and glucose deprivation (6.63 vs 6.77). We cannot, however, conclude from our measurements that the pH did not reach lower levels in the intracellular compartment, or in the extracellular space microenvironment in the cultures undergoing complete oxygen deprivation. When we raised the pH using Hepes buffered solutions, there was still no protection provided by MK-801 to damage induced by complete oxygen deprivation. The pH measured following oxygen deprivation in these experiments was 7.1, which should not cause marked NMDA receptor inactivation.

The glucose concentration used for maintaining hippocampal slice cultures is 33.6 mM in the growth medium and was the same concentration in the HBSS with glucose used for these experiments. To determine if the lack of protection with NMDA blockade was due to “hyperglycemic” conditions, which may worsen the acidosis produced during exposure, we repeated the anoxia experiment in HBSS containing a normal physiologic glucose concentration (5.6 mM). NMDA receptor blockade was still not effective in reducing neuronal damage of two different severity levels, caused by complete oxygen deprivation at this glucose concentration.

Other neuroprotective strategies which do not act primarily through glutamate receptors, did not exhibit similar differential neuroprotection between complete oxygen, and oxygen/glucose deprivation. These neuroprotective strategies included hypothermia, low chloride plus low calcium, and also free radical scavenging using PBN, and were all strongly neuroprotective in our model against CA1 damage induced by either combined oxygen and glucose deprivation or oxygen deprivation with glucose present. The neuronal protective effects of these treatments probably involves multiple mechanisms. Hypothermia has been shown to reduce ischemia induced glutamate release (Busto et al., 1989; Maher and Haschinski, 1993), as well as to preserve...
high energy phosphates during ischemia (Sutton et al., 1991) and thus preserve energy dependent calcium extrusion mechanisms (Kass and Lipton, 1982; Lipton and Lobner 1990). The involvement of ion fluxes in ischemic neuronal damage is supported by the neuroprotective effect of decreased chloride and calcium in the buffer solution during oxygen deprivation alone as well as by oxygen/glucose deprivation (Rothman, 1985; Goldberg et al., 1986; Friedman and Haddad, 1993). Decreased calcium in the extracellular fluid may attenuate the intracellular calcium surge seen with neuronal depolarization caused by energy deprivation through multiple mechanisms (Schurr and Rigor, 1992; Sejio, 1992), and also can protect against glutamate neurotoxicity (Choi, 1985, 1987). We used sodium gluconate to replace chloride with a nonpermeant anion, which has been shown by others to inhibit neuronal swelling due to depolarization (MacVicker and Hochman, 1991). Recently, increased production of free radicals has been reported to lead to membrane breakdown, and damage to cellular organelles resulting in cell death following ischemia (Sejio, 1992; Dawson et al., 1993; Sen and Phillip, 1993). Increases in intracellular calcium are thought to increase nitric oxide levels which can lead to excess free radical production (Sejio, 1992; Dawson et al., 1993; Dawson, 1994). Free radical spin trapping compounds such as PBN can reduce free radical levels, and have been shown to provide neuroprotection in an in vivo model (Clough-Helfman and Phillip, 1991; Sen and Phillip, 1993). The fact that these strategies were protective following both glutamate receptor mediated, and non-glutamate receptor mediated neuronal injury, suggests that they may influence separate common pathways leading to cell damage.

NMDA antagonists have been effective in reducing infarct size in focal ischemia models, suggesting that these compounds protect against partial energy deprivation which occurs in the ischemic penumbra (Wieloch et al., 1989; Sejio, 1992). NMDA receptor blockade has also been reported to reduce neuronal injury with partial oxygen (Goldberg et al., 1987; Marcoux et al., 1990). We therefore investigated the effects of NMDA receptor blockade on incomplete oxygen and glucose deprivation. These insults included glucose deprivation alone, partial oxygen deprivation (4% O2), and partial oxygen deprivation (4% O2), with complete glucose deprivation. The time of exposure was increased using each of these insults to attempt to induce a similar degree of damage which was observed after 35 min of complete oxygen and glucose deprivation. We found that NMDA receptor blockade effectively reduced neuronal injury produced by more prolonged exposure to insults which caused less severe energy deprivation, than complete oxygen and glucose deprivation (Table 4).

These experiments confirm that NMDA receptor antagonists can reduce CA1 injury caused by oxygen and glucose deprivation. These results also indicate that the presence of glucose during severe oxygen deprivation prevents the reduction of neuronal injury by glutamate receptor blockade. It remains to be elucidated why the presence of glucose prevents glutamate receptor blockade from reducing neuronal injury from severe anoxia. It is known that clinical situations exist such as anoxia from suffocation, carbon monoxide poisoning or other conditions where the cerebral circulation continues to supply glucose to the brain in the absence of oxygen. If the results from these experiments are directly applicable to these clinical situations, they may indicate that glutamate receptor blockade would be ineffective in reducing neuronal injury produced by insults where severe anoxia predominates. Further experiments using in vivo models are needed to determine if our results apply to these clinical situations.
